

38. Count and Say

Feb. 2, 2020 | 16.6K views

Average Rating: 3.67 (18 votes)

The count-and-say sequence is the sequence of integers with the first five terms as following:

1.	1
2.	11
3.	21
4.	1211
5.	111221

1 is read off as "one 1" or 11.
11 is read off as "two 1s" or 21.
21 is read off as "one 2, then one 1" or 1211.

Given an integer n where $1 \leq n \leq 30$, generate the n^{th} term of the count-and-say sequence. You can do so recursively, in other words from the previous member read off the digits, counting the number of digits in groups of the same digit.

Note: Each term of the sequence of integers will be represented as a string.

Example 1:

Input: 1
Output: "1"
Explanation: This is the base case.

Example 2:

Input: 4
Output: "1211"
Explanation: For n = 3 the term was "21" in which we have two groups "2" and "1", "2"

Solution

Overview

First of all, we would like to apologize to our audiences that the description of the problem is definitely not crystal clear, as many people have raised the issue in the discussion forum.

The problem should have been rather easy, as it is labeled, should it be stated clearly. That being said, let us consider the "mysterious" nature of the problem description as part of the challenge.

Imagine in a more challenging scenario, one might be given just a sequence of numbers without any explication, and one is asked to produce the next numbers, which would require one to figure out the hidden pattern about the generation of the sequence.

Now, the problem becomes more intriguing. And maybe some of you might want to pause for a moment to figure out the puzzle first before proceeding to the clarification.

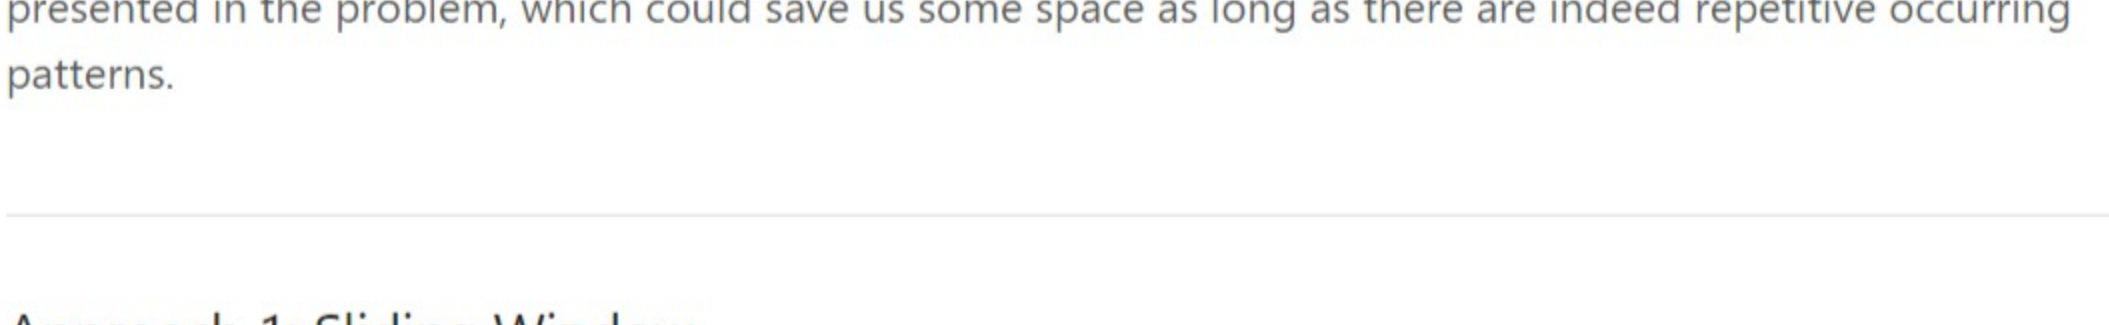

Sequence Puzzle

Before we proceed to the solutions, in this section, we would like to rephrase the problem.

Given two adjacent sequences of number, $[S_n, S_{n+1}]$, there exists a pattern that one can produce the sequence S_{n+1} from its previous sequence S_n .

More specifically, one can consider the sequence S_{n+1} as a sort of **summary** to its previous sequence S_n , i.e. S_{n+1} contains a list of pairs as [count, digit] which **encodes** all the information about its previous sequence S_n .

Let us take the sequence $S_4 = 1211$ as an example, from left to right, we then can divide the sequence into three sub-groups where each sub-group contains a list of identical and adjacent digit, i.e. $S_4 = \{1\}\{2\}\{11\}$, as shown in the following:

We then *count* the number of digits in each sub-group, and then output the summary in the format of [count, digit]. As the end, we would obtain the exact sequence of S_5 .

Sequence	Count	Digit
1	1	1
2	1	2
1	2	1

With the generated sequence S_5 , we then **recursively** apply the above rule to generate the next sequence.

Now that the description of the problem is clear, one might dismiss it as yet another strange and artificial problem to solve. Well, it is not true in this case.

Actually, we could consider this problem as a **naive compression algorithm** for a sequence of numbers. Instead of storing repetitive adjacent digits as they are, we could summarize them a bit with the method presented in the problem, which could save us some space as long as there are indeed repetitive occurring patterns.

Approach 1: Sliding Window

Intuition

Now that the problem has been clarified, the solution should be intuitive.

Following the rule as we described above, in order to generate the next sequence, we could scan the current sequence with a sort of **sliding window** which would hold the identical and adjacent digits. With the sliding window, we would divide the original sequence into a list of sub-sequences. We then count the number of digits within each sub-sequence and output the summary as pairs of [count, digit].

Algorithm

Here we define a function `nextSequence()` to generate a following sequence from a previous sequence, and we **recursively** call this function to get the desired sequence that is located at a specific index.

- Within the function, we scan the sequence with two contextual variables: `prevDigit` and `digitCnt` which refers to respectively the digit that we are expecting in the sub-sequence and the number of occurrence of the digit in the sub-sequence.
- At the end of each sub-sequence, we append the summary to the result and then we reset the above two contextual variables for the next sub-sequence.
- Note that, we use an artificial delimiter in the sequence to facilitate the iteration.

```
class Solution(object):
    def countAndSay(self, n):
        """
        :type n: int
        :rtype: str
        """
        return ''.join(self.nextSequence(n, ['1', 'E']))

    def nextSequence(self, n, prevSeq):
        if n == 1:
            return prevSeq[:-1]

        nextSeq = []
        prevDigit = prevSeq[0]
        digitCnt = 1
        for digit in prevSeq[1:]:
            if digit == prevDigit:
                digitCnt += 1
            else:
                # the end of a sub-sequence
                nextSeq.extend([str(digitCnt), prevDigit])
                prevDigit = digit
                digitCnt = 1

        # add a delimiter for the next sequence
        nextSeq.append('E')
```

Complexity

- Time Complexity: $O(2^n)$ where n is the index of the desired sequence.
 - First of all, we would invoke the function `nextSequence()` $n - 1$ times to get the desired sequence.
 - For each invocation of the function, we would scan the current sequence whose length is difficult to determine though.
 - Let us imagine in the worst scenario where any two adjacent digit in the sequence are not identical, then its next sequence would **double** the length, rather than having a *reduced* length. As a result, we could assume that in the worst case, the length of the sequence would *grow exponentially*.
 - As a result, the overall time complexity of the algorithm would be $O(\sum_{i=0}^{n-1} 2^i) = O(2^n)$.
- Space Complexity: $O(2^{n-1})$.
 - Within each invocation of the `nextSequence()` function, we are using a container to keep the result of the next sequence. The memory consumption of the container is proportional to the length of the sequence that the function needs to process, i.e. 2^{n-1} .
 - Though we were applying the recursion function, which typically incurs some additional memory consumption in call stack. In our case though, the recursion is implemented in the form of **tail recursion**, and we assume that the compiler could optimize its execution which would not incur additional memory consumption.
 - One could also easily replace the recursion with the iteration in this case.
 - As a result, the overall space complexity of the algorithm would be dominated by the space needed to hold the final sequence, i.e. $O(2^{n-1})$.

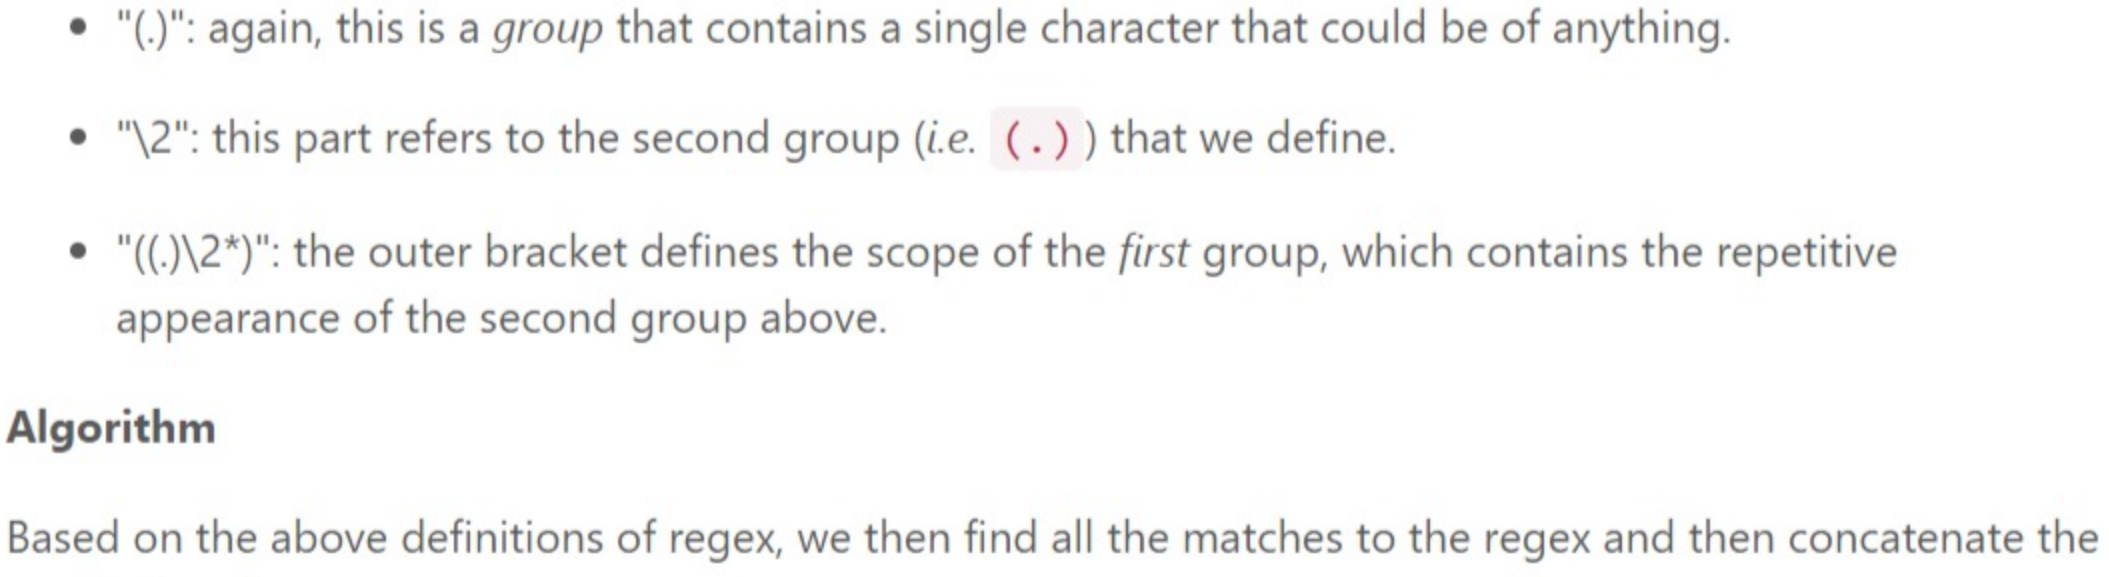

Approach 2: Regular Expression

Intuition

This problem could be a good exercise to apply **pattern matching**, where in our case we need to *find* out all those *repetitive* groups of digits.

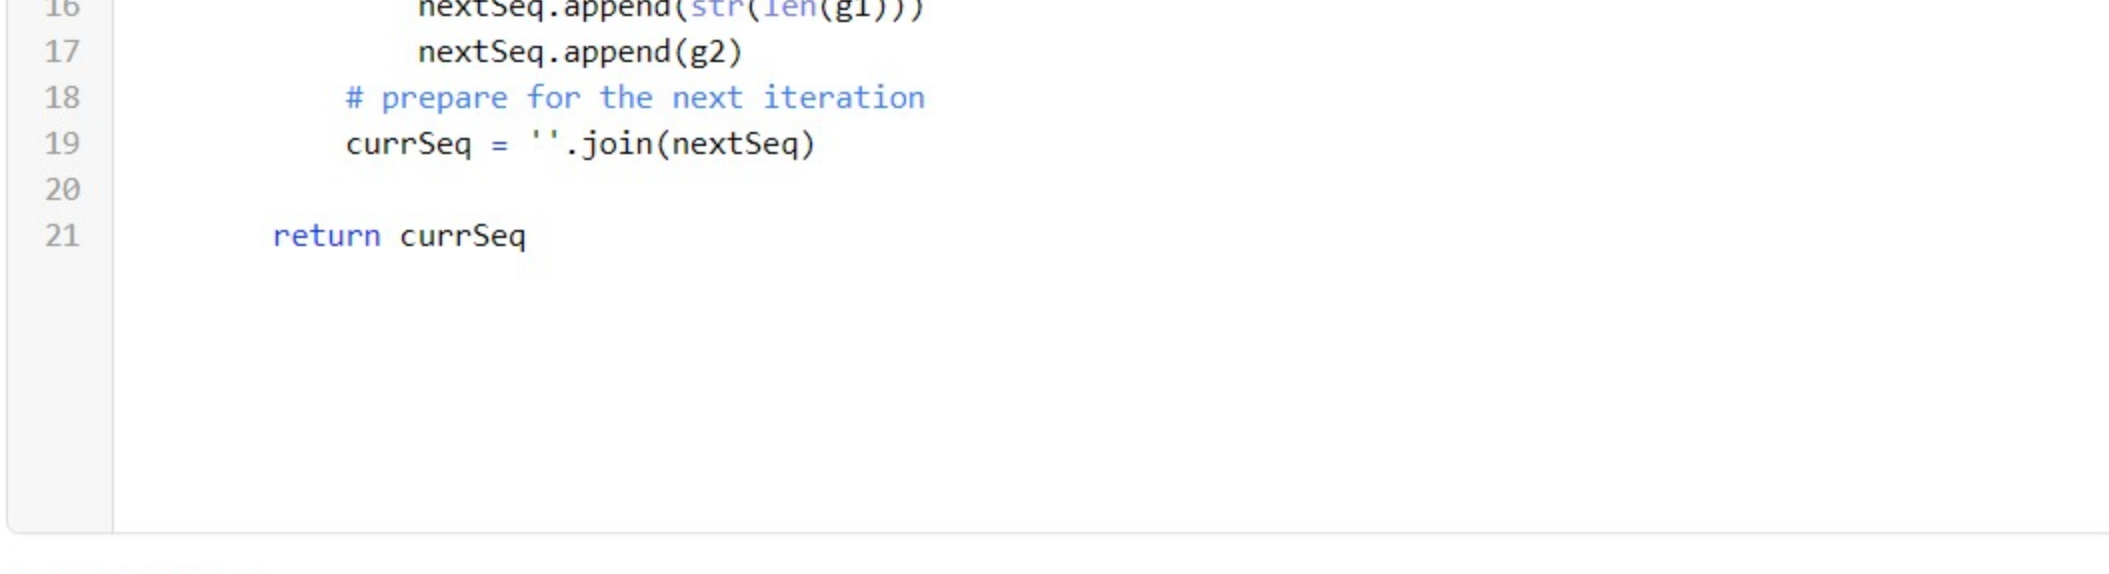

A **regular expression** (a.k.a *regex*) is a sequence of characters that defines a **search pattern**. The regex serves as a common tool for many pattern matching problems. And many programming languages provides regex capabilities either with build-in constructs or via some libraries.

Note that, although the syntax of regex is mostly universal across all programming languages, there might exist some subtle differences. Here we show two examples in Java and Python respectively.

We could break down the above regex expression into three 3 parts:

- "()": it defines a *group* that contains a single character that could be of anything.
- "\\1": this part refers to the defined group with the index of 1.
- "*": this qualifier followed by the group reference '\\1', indicates that we would like to see the group repeats itself *zero* or more times.

Slightly different than the above regex in Java, here we define two *groups* instead of one.

- "()": again, this is a *group* that contains a single character that could be of anything.
- "\\2": this part refers to the second group (i.e. `(.)`) that we define.
- "((.)\\2*)": the outer bracket defines the scope of the *first* group, which contains the repetitive appearance of the second group above.

Algorithm

Based on the above definitions of regex, we then find all the matches to the regex and then concatenate the results together.

```
class Solution(object):
    def countAndSay(self, n):
        """
        :type n: int
        :rtype: str
        """
        import re
        currSeq = '1'
        pattern = r'((.)\\2*)'
        for i in range(n-1):
            nextSeq = []
            for g1, g2 in re.findall(pattern, currSeq):
                # append the pair of count, digit
                nextSeq.append(str(len(g1)))
                nextSeq.append(g2)
            # prepare for the next iteration
            currSeq = ''.join(nextSeq)

        return currSeq
```

Complexity

- Time Complexity: $O(2^n)$ where n is the index of the desired sequence.
 - Similar with our sliding window approach, the overall algorithm consists of a nested loop.
 - We could assume that the time complexity of the regex matching is linear to the length of the input string.
 - As a result, the overall time complexity of the algorithm would be $O(\sum_{i=0}^{n-1} 2^i) = O(2^n)$.
- Space Complexity: $O(2^{n-1})$.
 - Within the function, we are using a container to keep the result of the next sequence. The memory consumption of the container is proportional to the length of the sequence that the function needs to process, i.e. 2^{n-1} .
 - As a result, the space complexity of the algorithm would be dominated by the space needed to hold the final sequence, i.e. $O(2^{n-1})$.

parth_berk ★56 April 21, 2020 8:14 AM @liaison why don't you change the question description instead of apologizing in the solution? lol

imml97 ★36 May 11, 2020 4:51 PM Explanation : https://leetcode.com/problems/count-and-say/discuss/621869/Finally-Understood-this-Explanation

MkKickass ★14 March 2, 2020 8:08 AM

vulpes95 ★1 May 17, 2020 4:02 PM Hi, I'm newbie in algorithms. Could you advice if my solution is O(2^n) or O(n^2)? I thought It's should be O(n^2)

lsheng_mel ★167 March 3, 2020 5:04 PM why the space complexity is not O(2^n) ? For both approaches, isn't the container created for every recursion/iteration, and it is proportional to the length of the sequence, so does not that make it O(1+2+2^2+2^3+...+2^n-1)=O(n)? @liaison thanks!

mrkrispy ★1 June 18, 2020 7:52 AM I didn't like the fact that the first approach was recursive. Since recursive functions use more memory. Though the recursive function is much more easier to read. This code does not use the regex method, but I haven't memorized regex for python. I also don't know if regex is allowed for interviews.

ashiksingh ★7 May 6, 2020 9:22 PM I don't follow. Isn't an n^2 solution possible using dynamic programming , similar to how DP fibonacci is generated ?

lidaivet ★80 April 15, 2020 5:12 AM How come a O(n^2) solution isn't provided? I believe this can be solved at n^2. But I could be wrong.

tkblackbelt ★12 April 3, 2020 3:37 PM Used a queue to process the numbers in FIFO order.

Would the Time Complexity of this be O(N*S) where N is the number of sequences we need to go through and S being the while loop over the values?

liaison ★5615 March 5, 2020 1:05 AM hi @lsheng_mel you're right about the size of the container for each recursion/iteration. But it is just that the container that we used for each iteration/recursion would be destroyed and recycled later. The space complexity of an algorithm is the maximal size of memory used for any given moment, but not the accumulative allocation of memory. So we just need O(2^(n-1)) memory to run the algorithm.
